= Abstract =

Herpes zoster in infancy is very rare but can be developed following intrauterine or postnatal exposure to varicella zoster virus. We report a case of herpes zoster in a 4-month-old male infant. He had no prior history of primary varicella or varicella vaccination. His mother had no history of varicella infection and no contact history with varicella during pregnancy. He had a history of exposure to his father with herpes zoster 3 months ago and to his cousin with convalescent chickenpox 2 months ago. Multinucleated, giant cells were shown on a Tzanck smear. He was treated with acyclovir and first generation cephalosporin for herpes zoster with Staphylococcal skin infection, with complete resolution without sequelae. (Korean J Pediatr 2008; 51:1368-1371)

Key Words: Herpes zoster, Infant

Introduction

Herpes zoster is caused by reactivation of varicella zoster virus (VZV) from the dorsal sensory ganglia or the cranial nerve ganglia after a previous primary infection with chickenpox. It is known that pediatric zoster rarely occurs and usually not so severe when it develops, except in immunocompromised children. In particular, herpes zoster in infancy is very rare but can be developed following intrauterine or postnatal exposure to VZV. To our knowledge, there were only 5 cases of infantile herpes zoster reported in Korea.

We describe an uncommon case of herpes zoster in a 4-month-old infant, not following symptomatic varicella infection. In addition, we also review the literature on herpes zoster in infants reported in Korea.

Case report

A 4-month-old male infant presented to the emergency department with a 2-day history of erythematous vesicles on the right side of his chest and back. He was born at 40 weeks gestation, with a birth weight of 3,450 g. The child had been eating, sleeping well, and remained afebrile. His mother had no history of varicella infection and no contact history with varicella during pregnancy. The patient had a history of exposure to his father with herpes zoster corresponding to the left C7 dermatome 3 months ago, and to his cousin with convalescent chickenpox 2 months ago. The infant had neither a history of febrile illness nor of symptoms that appeared to be primary varicella. Initial physical examination of the infant showed grouped vesicles and crusts on an erythematous based scattered along the chest and back, with a sharp demarcation at the midline. This corresponded to the right T4 dermatome (Fig. 1). There was a yellowish discharge from the lesion. No other abnormalities were noted. He was admitted for treatment of possible bacterial superinfection complicating herpes zoster. Findings from a Tzanck smear were positive for multinucleated giant cells.

Complete blood cell count with differential count was within normal limit. Immunologic work-up was undertaken. Quantitative serum immunoglobulin levels were as follows: IgA, 38 mg/dL (normal range, 8-90 mg/dL); IgM, 73 mg/dL (normal range, 10-90 mg/dL); and IgG, 583 mg/dL (normal range, 200-1,200 mg/dL). Lymphocyte subset analysis revealed normal ratios of CD3, CD4, CD8, CD19, CD16, and CD56 surface markers. Methicillin-sensitive Staphylococcus

Aureus was isolated from the skin lesions. Serologic tests obtained on admission were positive for anti-VZV IgG, but negative for anti-VZV IgM.

The patient was received intravenous therapy, including acyclovir and first generation cephalosporin. He showed improvement in the eruption and exudates, and was discharged to home after 4 days. He recovered completely without sequelae, and has remained well.

**Discussion**

Primary varicella tends to occur in childhood, whereas herpes zoster is a disease of adults, with most patients being older than 45 years[1,3]. The incidence of herpes zoster is very low in the group 0 to 5 years of age (20 per 100000 person-years) compared with adolescents or adults[9]. In Korea, Park et al. reported that children under 18 years old constituted 5.7% (17/327) of total herpes zoster patients, and 18% (13/72) of the children were aged 4 years and younger[10].

Herpes zoster in healthy immunocompetent children in early childhood or during intrauterine exposure is associated with the immaturity of the immune system[11,12]. It has been reported that, infants had a lower response of VZV-specific cellular and humoral immunity than older children after primary varicella, and the low response of specific immunity provide a possible explanation for the finding that chickenpox in infancy is a risk factor for the development of herpes zoster in otherwise healthy children[13,14].

Infantile herpes zoster has been described following intrauterine exposure to VZV[5]. Virus-specific immunoglobulin detection is uncommon in the fetal stage, and the frequency of lymphocytes, natural killer cells, cytokine mediators responding to herpetic antigens is low in infants[15,16]. These may result in the difficulty of maintaining virus latency with an increased risk of developing zoster in the infant period[17]. Intrauterine VZV exposure can result in asymptomatic congenital infection with subsequent herpes zoster within the first year of life[2]. Intrauterine VZV infection can cause congenital varicella syndrome, acute varicella at birth, or herpes zoster in infancy[18]. In addition, infantile herpes zoster can occur after postnatal exposure to VZV, but postnatally acquired herpes zoster is less common than intrauterine infec-

tion. It has been suggested that protective maternal VZV antibodies passively transferred to the infant may modify the disease into a subclinical varicella and that subclinical form of primary varicella infection may predispose to herpes zoster. In general, infants with primary varicella infection are at high risk for herpes zoster within the first year of life.

In this case, the patient was exposed to his father with herpes zoster 3 months ago, and to his cousin with convalescent chickenpox 2 months ago. Varicella can develop in a nonimmune individual after exposure to cases of varicella or zoster. In this case, thereafter, the patient might develop subclinical form of primary varicella infection from his father with herpes zoster or his cousin with chickenpox, and subsequently present clinically with herpes zoster. There were no reported varicella exposures or infection to the patient’s mother during pregnancy, but this cannot be conclusively ruled out.

Summaries of the reported Korean cases of herpes zoster in the first year of life are presented in Table 1. There were 2 cases (33%) of prenatal acquisition and 4 cases (67%) of postnatal acquisition. Male to female ratio was 1:1. The locations were thoracic dermatomes in all patients. According to reports by Kurlan et al., of the 62 cases, 43 cases (69%) were prenatal exposure and 19 cases (31%) were postnatal exposure. In their study, of the cases in which patient sex was reported, 60% occurred in boys and 40% in girls. They reported that the dermatomes most frequently affected are thoracic dermatomes (33%), but all dermatomes are nearly equally affected. Cranial nerves were involved in 27%, cervical in 20%, and lumbosacral dermatomes in 20%. In another study of Korean children, the dermatomal involvements of herpes zoster were most commonly on thoracic dermatomes.

Oral (40–60 mg/kg per day) or intravenous (30 mg/kg per day) acyclovir has been used for 5 to 8 days or for 2 days after new lesions stop developing for VZV in children. It is well known that children with herpes zoster have a better prognosis than adults, with milder symptoms and less complication. In this case, the patient had no other symptoms than skin lesion, and complete resolution occurred without sequelae. In cases of infantile herpes zoster reported in Korea, a patient had developed pneumonia but subsided. All patients treated with acyclovir and healed completely without sequelae.
