Pleomorphic Adenoma of the Trachea
—A case report—

Hyo Chae Paik, Sang Hyun Lim, Doo Yun Lee, and So Yah Paik*

An unusual tracheal tumor was found in a 50 year old male who was admitted due to mild dyspnea on exertion. Simple chest X-ray showed an abnormal mass shadow in the trachea and computerized chest tomogram revealed a tumor in the mid 1/3 of the trachea obstructing 80% of the lumen. Through a right thoracotomy incision, resection of a 2.5cm segment of the trachea with end-to-end anastomosis was done and microscopic findings showed many cystic spaces with myxomatous hyalinous stroma. It was diagnosed as a pleomorphic adenoma of the trachea.

Key Words: Pleomorphic adenoma, end to end anastomosis

Primary tracheal tumors are rare disease entities (Moersch et al. 1954; Salm,1964) and squamous cell carcinoma is the most common epithelial tumors encountered (Houston et al. 1969). Other epithelial tumors are that from the glandular tissue within the tracheal wall and it is histologically identical to tumors from the major salivary glands of the oral cavity, pharynx, nasopharynx, and respiratory tract. Among these is the adenoid cystic carcinoma, mucoepidermoid carcinoma, and pleomorphic adenoma or benign mixed tumor (Salm, 1964; Hajdu et al. 1970). Pleomorphic adenoma is extremely rare and as of 1988, only 16 cases have been reported in literature (Hemmi et al. 1988).

We report a case of pleomorphic adenoma of the trachea with a review of the literature.

REPORT OF A CASE

A 50 year old male was admitted to the hospital due to mild dyspnea on exertion for a period of three months. On physical examination, the lung sounds were clear and he was well fit for his age. Laboratory studies were unremarkable except for the pulmonary function test which revealed an obstructive defect. The chest X-ray showed normal lung parenchyma but a round mass in the mid trachea was clearly seen (Fig. 1, 2). Computed tomography of the chest showed a 1.5×1.7×1.8 cm sized homogenous mass protruding from the right inner wall of the trachea obstructing 80% of the tracheal lumen 4 cm above the carina (Fig. 3). Due to severe obstruction of the airway by mass, bronchoscopy was not performed because of high risk and therefore an operation was performed without bronchoscopy.

Under general anesthesia, right posterolateral thoracotomy was done and the trachea was dissected from the surrounding organ and the obstructing mass was palpable. After circumferential resection of 4 tracheal rings including the tumor, reconstruction of the trachea

by end-to-end anastomosis with interrupted Vicryl 4-0 suture was performed. The gross findings showed the tracheal lumen obstructed by a firm, glistening, yellowish tumor originating from the posterior membranous part and the tumor was 1.8 cm in diameter with no signs of invasion of the surrounding tissue. The resected trachea contained a solid, polypoid mass measuring 2×2 cm which was completely covered by glistening mucosa. The mass occupied about 90% of the total tracheal lumen (Fig. 4). On cut section, it reveals to be composed of solid, gray-white homogeneous

tissue with a slight myxoid tinge. There was no evidence of necrosis or hemorrhage.

Microscopically, the tumor was found within the lamina propria encircled by a thin fibrous capsule (Fig. 5). Solid sheets of epithelial cells are seen scattered in the background of the myxoid stroma with gradual immersing of these epithelial cells within the myxoid stroma (Fig. 6). Focal areas also show tubular arrangement of these epithelial components, but neither mitosis nor necrosis was present and these findings were compatible with a typical pleomorphic adenoma.

The chin and the anterior chest was immobilized by two heavy nylon sutures in-between to relieve tension at the anastomosis site. The postoperative course was uneventful, and bronchoscropy performed on postoperative 18th day showed clear, well healed anastomotic site and the patient was discharged in good general condition.

**DISCUSSION**

The tracheal tumors are rare and when encountered, it is usually squamous cell carcinoma or adenoid cystic carcinoma. Pleomorphic adenoma occurring in the trachea is very rare and only 16 cases have been reported in literature. Pleomorphic adenoma is a common tumor found in the salivary glands of the oral cavity, pharynx, nasopharynx, and the respiratory tract, and it is characterized histologically by many cystic spaces and hyaline connective stroma which is also found in adenoid cystic carcinoma.

Ma et al. (1979) reviewed 14 cases of tracheal pleomorphic adenoma that has been reported since 1922, and two more cases have been reported (Sano et al. 1984; Hemmi et al. 1988) since. The ages varied from 26 to 76 years and they complained of hemoptysis, cough, asthma, and dyspnea. There were 10 male and 6 female and 7 cases (43.7%) occurred in the upper 1/3 of the trachea, 6 cases (37.5%) in the middle 1/3, 2 cases (12.5%) in the lower 1/3, and unknown in 1 case.

The tumor has to be distinguished from more commonly occurring squamous cell carcinoma and adenoid cystic carcinoma. It is easily differentiated from the squamous cell carcinoma by circumscribed, elevated, nodular appearance which is commonly seen in pleomorphic adenoma, but when a specific cartilaginous component is not visible, it is difficult to differentiate from the adenoid cystic carcinoma. The most important differential point from the adenoid cystic carcinoma is that adenoid cystic carcinoma shows cell nests that are sharply separated from the connective tissue as to the gradual transition between the epithelium and stromal elements seen in the pleomorphic adenoma (Sano et al. 1984). According to Regezi et al. (1985), immunoreactivities of S-100 protein and GFAP (glial fibrillary acidic protein) in 33 cases of salivary gland tumor was observed and all 17 pleomorphic adenomas showed strong positive reactions to S-100 protein and GFAP compared to only weak reactions for S-100 in adenoid cystic carcinoma.

Therefore S-100 and GFAP may be helpful markers in differentiating pleomorphic adenoma and adenoid cystic carcinoma.

Surgical excision is the optimal treatment for pleomorphic adenoma and it is probably curative. However, there has been one case of malignant pleomorphic adenoma reported by Hemmi et al. (1988). This patient underwent a complete resection of the tracheal tumor which was diagnosed as pleomorphic adenoma, and after 11 years, the patient was seen with the metastatic lesion in the lung and the chest wall. Therefore, pleomorphic adenoma of the trachea can not be conclusively called a benign tumor.

Since only a few cases of pleomorphic adenoma have been reported in literature, further accumulation of cases are necessary in order to define its biological behavior and clinical course of this disease.
