Superficial acral fibromyxoma (SAFM) is a rare myxoid tumor that was first described in 2001. The presence of a very slow growing solitary tender mass in the subungal area is the typical clinical feature at presentation. SAFM is composed of stellate cells in a myxocollagenous matrix with a poorly circumscribed margin. This tumor is thought to be benign, but its natural course is not fully understood. We describe a 15-year-old patient with recurrent SAFM and discuss the proper treatment and follow up.

CASE REPORT

A 15-year-old female presented with a slow growing lesion on the right index finger that formed three years previously. The patient reported that the nodule was tender and this made it hard to grasp a pen. The physical examination revealed that the nodule was mainly located in the subungal area and extended to the lateral nail fold where it disrupted the nail plate (Fig. 1). Illumination of the nodule with light showed no transparency, so it was not suspected to be a cystic lesion. Instead, the nodule was hard and fixed to the underlying tissue on palpitation. The plain x-ray radiograph was normal. The past medical and family history was noncontributory.

An incisional biopsy was performed after removal of the nail plate, under local anesthesia. Healing of the biopsy wound was planned by secondary intention due to its location. A nodule that was about 0.5 cm in size was incised from the lesion. The histopathological examination revealed that the tumor was located underneath the epidermis and was poorly circumscribed by the surrounding dermis (Fig. 2A). In the tumor, there was a collagen bundle that was filled with abundant myxoid material and stellate or fibroblast-like cells (Fig. 2B). These stellate cells with oval shaped plump nuclei and reticulated basophilic cytoplasm had a fascicular growth pattern that was observed by high power microscopy (Fig. 2C). Pleomorphism or mitotic figures were not noted. Few mast cells were found in the tumor. However, there was proliferation of the blood vessels accentuated in the highly mucinous area. Immunohistochemical staining revealed that the satellite cells were positive for CD34, epithelial membrane antigen (EMA) and vimentin, but negative for actin, desmin and S100. The results supported the diagnosis of a SAFM.

The patient was followed for two years. The biopsy site healed well. However, a recurrent tumor was noted 1 year 8 months after the initial procedure. The recurrent lesion

INTRODUCTION

Superficial acral fibromyxoma (SAFM) is a recently defined myxoid tumor with predilection for forming sub or periungual lesions. This tumor usually presents as a slow growing tender mass in adult males. Histologically, it is a poorly circumscribed mass mainly composed of spindle or stellate neoplastic cells that show a variable degree of pleomorphism in a myxocollagenous stroma. The spindle cells have immunoreactivity for CD34, CD99, vimentin and focally for the epithelial membrane antigen. Blood vessels are predominant in the myxoid area and mast cells are scattered throughout the lesion. The natural course of SAFM is assumed to be benign from prior reports. We report a case of recurrent SAFM with follow up for two years.
A Case of Recurrent Superficial Acral Fibromyxoma

Fig. 1. The tender, growing subungual lesion and the distorted nail plate. The right side of the nail plate looked pale because of the pressing margin of the tumor.

Fig. 2. (A) Poorly circumscribed dermal tumor with myxoid and fibrous areas (H&E, ×40). (B) Stellate or fibroblast-like cells showing a fascicular growth pattern (H&E, ×100). (C) Stellate cells with an elongated thin cytoplasm were noted in the collagenous and mucinous areas. Blood vessels proliferated focally. (H&E, ×200).

was slowly increasing in size, and the size at the two year follow up was similar to the first lesion (Fig. 3). We then planned to completely extirpate the lesion.

DISCUSSION

Since Fetsch et al. first described a SAFM in 2001, additional cases have been reported. However, the natural

ND: not described.

course of this lesion is not fully known\(^2\). SAFMs arise in
the nail region and are commonly found on the toes of
adult males. Onset in younger patients is not common
according to the medical literature. Preceding trauma has
been noted in a minority of the cases. The mass usually is
tender and can have a long duration of up to 30 years
before presentation. The tenderness varies and is not
severe in all cases\(^1\). Rarely this lesion also occurs on the
ventral surface of a finger or toe\(^1\).\(^5\). The reported cases are
summarized in Table 1.

Histopathologically, this distinctive tumor is composed of
stellate shaped and spindled fibroblast-like tumor cells in a
variable degree of admixed myxoid or collagenous
matrices. As the tumor persists, the collagenous matrix has
a tendency to become predominant over the myxoid
matrix\(^1\). The stellate cells show a loose storiform, and a
fascicular or random growth pattern. Mild nuclear atypia
or pleomorphism of the stellate cells is present, but

atypical mitotic figures are absent. Typically the satellite
cells are positive for CD34, CD99, vimentin and focally
for EMA; however, the results of the EMA are not a
consistent finding\(^2\). The proliferation of blood vessels
is noted in the myxoid area and the mast cells are easily
identified. The margin of the tumor is not circumscribed,
but grossly shows a lobular pushing or infiltrative margin.
Tumor involvement of the periosteal region has been
described\(^1\).\(^3\).\(^6\).

The differential diagnosis for an acral soft tissue tumor
includes myxoid dermatofibrosarcomas protuberans, myxoid
neurofibromas, myxoid fibrous histiocytomas, low grade
myxofibrosarcomas and acquired digital fibrokeratomas.
Myxoid dermatofibrosarcomas protuberans are rare, but
the histological features are similar. CD34 positive
uniform spindle cells with a focally tight storiform in a less
mucinous area that infiltrates the subcutis are charac-
teristics of a myxoid dermatofibrosarcoma protuberans. A
negative result on EMA testing is helpful for the differentiation from SAFMs. In the case of incomplete excision, local recurrence is likely, as is a malignant neoplasm. In myxoid neurofibromas, the immunoreactivity to S100 as a marker for neural origin and the lack of vasculature in the tumor mass distinguish them from SAFMs. Myxoid fibrous histiocytomas contain spindle cells in the storiform as well as sclerotic collagen at the periphery of the lesion. The myxoid area is not as abundant as it is in SAFMs, and it has positive immunoreactivity for factor XIIIa antigen, but not for CD34. Low grade myxofibrosarcomas contain small stellate cells with pleomorphic nuclei around the blood vessels and pseudolipoblasts. Acquired digital fibrokeratomas are mainly composed of paucicellular vertically interwoven collagen bundles with a collarle. The natural course of SAFM appears to be benign. However, the histopathological spectrum of stellate tumor cells ranges from mild to pronounced nuclear atypia with mitotic figures. Therefore, transformation of a SAFM to a low grade malignant tumor is possible. Clinically, local recurrence without evidence of distant metastasis was noted only in one patient among the reported cases. Thus, complete excision with adequate margins is mandatory. Furthermore, follow up is necessary because of its slow growing nature and possible recurrence.

In conclusion, SAFMs are rare neoplasms that have been recently defined. The possibility of a SAFM should be considered when a patient presents with a slow growing tender periungual mass. Regarding the treatment, excision of the mass is necessary, but the mass may recur and therefore follow up is needed. This case illustrates the recurrence of a SAFM and the need for long-term follow up.
