CASE REPORT

A Case of Perifollicular Fibroma

Jae-Hui Nam, M.D., Joon Hong Min, M.D., Ga-Young Lee, M.D., Won-Serk Kim, M.D.

Perifollicular fibroma (PFF) is a very rare proliferative lesion of the perifollicular sheath. A flesh-colored, dome-shaped papulonodule is usually located on the face or the neck. These papulonodules may be single or multiple. Histologically, the lesion consists of a concentric arrangement of cellular fibrous tissue around a normal hair follicle. We describe here an unusual case of PFF in a 41-year-old female who had an asymptomatic small skin colored papule on the scalp, and this is an uncommon location for PFF.

INTRODUCTION

Perifollicular fibroma (PFF) is a rare cutaneous hamartoma that shows differentiation in the connective tissue sheath of hair follicles. It can occur as a solitary papule or as multiple lesions. Multiple PFF lesions have been linked to adenomatous colonic polyps and they may be inherited as an autosomal dominant trait. Histologically, the lesion consists of a concentric arrangement of cellular fibrous tissue around a normal hair follicle. To the best of our knowledge, most reports have described multiple PFF lesions involving the scalp. A solitary PFF lesion on the scalp is a very rare phenomenon.

We herein report on a case of a solitary PFF lesion arising from the scalp of a 41-year-old female.

CASE REPORT

A 41-year-old woman presented with an asymptomatic dome-shaped cutaneous papule on the scalp, and she’d had this lesion for 5 years. The lesion had started as a tiny papule that had slowly enlarged. Her past medical and family history was unremarkable. On physical examination, a 0.5×0.5 cm sized, single, soft flesh colored papule was noted on the scalp (Fig. 1). An excision biopsy was taken. Histopathologic examination of the excised specimen showed concentric layers of fibrous connective tissues around a well-formed hair follicle and a mild mononuclear infiltrate in the perifollicular area (Fig. 2). Masson’s trichrome staining showed its marked perifollicular sheath (Fig. 3). The perifollicular spindle cells were positive for CD34 (Fig. 4). The elastic tissue staining was negative. The diagnosis of PFF was made based on these findings. No evidence of recurrence was noted after a follow-up period of 10 months.

DISCUSSION

Perifollicular fibroma (PFF) was first described by Burnier...
and Rejsek⁶ in 1925. It is characterized by skin-colored, dome-shaped, smooth, firm, 1 to 5 mm sized papules⁷. They mostly present on the face and neck region¹. Multiple PFFs may be associated with Birt-Hogg-Dubé syndrome and internal diseases such as colonic polyps, polyposis and cancer. The lesion in our case was a solitary small, soft, skin-colored papule located on the scalp. PFF is a very rare disease whether it presents as a single lesion or multiple lesions¹. This is an interesting case because the diagnosis could have been missed. Solitary PFF usually presents on the face and neck, and involvement of the scalp is extremely rare⁵.

The etiology is currently unclear, but several hypotheses have been proposed. Zackheim and Pinkus² suggested a neoplastic origin. Freeman and Chornosky⁸ observed the ultrastructure of a PFF that was present at birth in a male infant and this supported the hypothesis of a tumor derivation as opposed to a reactive etiology. But the possibility that a PFF may simply represent a fibroblastic response to previous follicular inflammation can not be excluded.

Headington⁹ described that some PFFs represent an exaggerated response to inflammation or irritation. Balfour and Smoller⁵ also supported the theory of reactive...
fibroplasia.

Histopathologically, PFF shows concentric proliferations of collagen fibers surrounding a normal hair follicle. The differential diagnoses include fibrofolliculoma, trichodiscoma, fibrous papule, dermatofibroma and neurofibroma. In contrast to PFF, a distorted hair follicle in fibrofolliculoma is surrounded by a fibrous stroma. Multiple thin, anastomosing bands of follicular epithelium extend into the stroma. Trichodiscoma and fibrous papule do not show a concentric arrangement of perifollicular collagen. Dermatofibroma is comprised of spindle cells that show no predilection for the follicle, and dermatofibroma lacks an epithelial component. Neurofibroma exhibits a collection of bland spindle cells with elongated, wavy nuclei and wavy collagenous strands, and this lesion shows no particular association with the hair follicle. Meticulous assessment of serial sections of the specimen is important to arrive at a definitive diagnosis for suspected cases because the histologic features of PFF do not encompass uniform changes in all hair follicles. Elastic stain could help to determine the origin of the lesion. It has been suggested that reduced elastic fibers with collagenous overgrowth can represent a neoplastic process. The immunohistochemical features of PFF, which consist of CD34-positive spindle cells and factor XIIIa-positive dendritic cells within the connective tissue component, could be associated with preceding inflammatory conditions in PFF. In our case, we could not identify any preceding events that could have led to inflammation, and the histology showed an accentuated perifollicular sheath and a marked decrease in elastin. These findings may represent a tumor derivation rather than a reactive etiology.

We report here on a rare case of solitary PFF that occurred on the scalp of a 41-year-old Korean woman.
