Mutations in genes encoding ion channels, transporters, exchangers, and pumps in human tissues have been increasingly reported to cause hypokalemia. Assessment of history and blood pressure as well as the K⁺ excretion rate and blood acid-base status can help differentiate between acquired and inherited causes of hypokalemia. Familial periodic paralysis, Andersen’s syndrome, congenital chloride-losing diarrhea, and cystic fibrosis are genetic causes of hypokalemia with low urine K⁺ excretion. With respect to a high rate of K⁺ excretion associated with faster Na⁺ disorders (mineralocorticoid excess states), glucocorticoid-remediable aldosteronism and congenital adrenal hyperplasia due to either 11β-hydroxylase and 17α-hydroxylase deficiencies in the adrenal gland, and Liddle’s syndrome and apparent mineralocorticoid excess in the kidney form the genetic causes. Among slow Cl⁻ disorders (normal blood pressure, low extracellular fluid volume), Bartter’s and Gitelman’s syndrome are most common with hypochloremic metabolic alkalosis. Renal tubular acidosis caused by mutations in the basolateral Na⁺/HCO₃⁻ cotransporter (NBC1) in the proximal tubules, apical H⁺-ATPase pump, and basolateral Cl⁻/HCO₃⁻ exchanger (anion exchanger 1, AE1) in the distal tubules and carbonic anhydrase II in both are genetic causes with hyperchloremic metabolic acidosis. Further work on genetic causes of hypokalemia will not only provide a much better understanding of the underlying mechanisms, but also set the stage for development of novel therapies in the future.

Key Words: acid-base equilibrium; aldosterone; blood pressure; genes; hypokalemia; mutation; renin; urine electrolyte

Introduction

Potassium (K⁺), a major intracellular cation, is critically important in maintaining the osmotic equilibrium of the cell and electrical gradient across the cell membrane. Most of the cellular K⁺ in the body resides in the intracellular fluid (ICF) (~50 mEq/kg, 98%), largely in the skeletal muscles (3,000 mEq), red blood cells (300 mEq), and liver (200 mEq). In contrast, the total K⁺ content in the extracellular fluid (ECF) is very low (<1 mEq/kg, approximately 2%) and similar to the daily dietary intake and renal excretion of K⁺. Plasma K⁺ concentration is a function of total body K⁺ and the distribution between intracellular and extracellular stores. Hypokalemia, defined as plasma K⁺<3.5 mEq/L, is the most common electrolyte abnormality encountered in clinical practice and usually arises from redistribution of K⁺ from ECF to ICF stores and/or total body K⁺ depletion. The most significant effects of hypokalemia are cardiovascular, neuromuscular, renal, and metabolic, thus associated with higher morbidity and mortality. Prompt diagnosis with appropriate management of hypokalemia avoids
unnecessary testing and potential dire complications. The treatment of hypokalemia involves weighing the degree and timing of hypokalemia with clinical manifestations, underlying causes, associated conditions, and risks during therapy.

With the unprecedented progress in molecular and genetic analysis, many previously confusing phenotypic features of the inherited disorders can now be understood. Of note, although hypokalemia in these genetic disorders may be the foremost finding, one should understand that hypokalemia per se is not a specific disease but an associated finding in a large number of different diseases. An accurate diagnosis will help determine the molecular defect if the basis for hypokalemia is a genetic disorder. In this paper, our approach to hypokalemia is introduced and the genetic causes of hypokalemia are discussed to provide some insights in the field.

**K⁺ homeostasis**

K⁺ concentration in the ICF is close to 35-fold greater than in the ECF and daily K⁺ intake is approximately equal to the amount of K⁺ in the ECF. Maintaining normal serum K⁺ concentration in the ECF requires tight regulation of the distribution of K⁺ between the ICF and ECF (internal K⁺ balance) and renal K⁺ excretion (external balance). Derangements in either the internal balance (e.g., K⁺ shift) or external balance (e.g., K⁺ wasting) can result in hypokalemia.

1. Regulation of K⁺ between ICF and ECF

1) Driving force

The force driving K⁺ shift into cells is the more negative voltage in cells. This is created by the Na⁺,K⁺-ATPase. Na⁺,K⁺-ATPase extrudes three sodium ions (Na⁺) for every two K⁺ ions that enter cells, thus producing a net export of positively charged ions. The main hormones that increase the activity of Na⁺,K⁺-ATPase include β₂-adrenergic agonists, insulin, and thyroid hormone. Na⁺,K⁺-ATPase is activated by β₂-adrenergics, insulin and thyroid hormone, which causes the electroneutral entry of Na⁺ into cells and thus the net exit of positive voltage via the Na⁺,K⁺-ATPase, is also activated by insulin. K⁺ channels which permit K⁺ exit is responsible for generating the majority of the resting membrane potential and blocked by barium. The barrel shaped structures represent the terminal CCD (lower panel). The reabsorption of Na⁺ faster than Cl⁻ (right) or Cl⁻ slower than Na⁺ (left) in the CCD creates the lumen negative voltage that drives the net secretion of K⁺. Fast Na⁺ disorders cause extracellular fluid (ECF) volume expansion and high blood pressure, whereas, slow Cl⁻ disorders lead to diminished ECF volume and low to normal blood pressure. ENaC, epithelial Na⁺ channels.

2) K⁺ channels

K⁺ channels are a diverse and ubiquitous family of

---

**Fig. 1. Regulation of K⁺ redistribution in cells and K⁺ secretion in the cortical collecting duct (CCD).** The circle depicts the cell membrane (upper panel). Na⁺,K⁺-ATPase, Na⁺/H⁺ exchanger (NHE), and K⁺ channels are three major elements controlling K⁺ shift. Na⁺,K⁺-ATPase is activated by β₂-adrenergic agonists, insulin and thyroid hormone. NHE, which causes the electroneutral entry of Na⁺ into cells and thus the net exit of positive voltage via the Na⁺,K⁺-ATPase, is also activated by insulin. K⁺ channels which permit K⁺ exit is responsible for generating the majority of the resting membrane potential and blocked by barium. The barrel shaped structures represent the terminal CCD (lower panel). The reabsorption of Na⁺ faster than Cl⁻ (right) or Cl⁻ slower than Na⁺ (left) in the CCD creates the lumen negative voltage that drives the net secretion of K⁺. Fast Na⁺ disorders cause extracellular fluid (ECF) volume expansion and high blood pressure, whereas, slow Cl⁻ disorders lead to diminished ECF volume and low to normal blood pressure. ENaC, epithelial Na⁺ channels.
membrane-spanning proteins that selectively conduct $\text{K}^+$ ions across the cell membrane along its electrochemical gradient in both excitable and non-excitable cells$^6$. There are several different types of $\text{K}^+$ channels. These $\text{K}^+$ channels share the common features of a water-filled permeation pore allowing $\text{K}^+$ ions to flow across the cell membrane, a selectivity filter that specifies $\text{K}^+$ as the permeant ion species, and a gating mechanism that serves to switch between open and closed channel conformations. Because $\text{K}^+$ ions do not reach diffusion equilibrium, control of the open-probability of $\text{K}^+$ channel regulates the transmembrane voltage. $\text{K}^+$ channels are inhibited by barium and other drugs$^6$. Closure or opening may not only alter the membrane potential, but also acutely affect the plasma $\text{K}^+$ concentration.

2. Renal handling of $\text{K}^+$

Most of the filtered $\text{K}^+$ is reabsorbed by the proximal tubule and the loop of Henle. The final amount of $\text{K}^+$ excreted in the urine is primarily controlled by the late distal convoluted tubule (DCT), the connecting tubule, and the cortical collecting duct (CCD)$^7$. Two factors influence the rate of $\text{K}^+$ excretion: the flow rate in the terminal CCD and the net secretion of $\text{K}^+$ by principal cells in the CCD which raise the luminal concentration of $\text{K}^+$ ([K$^+$]$_{\text{CCD}}$) (Fig. 1). There is an interplay between the magnitudes of the flow rate in the CCD and the [K$^+$]$_{\text{CCD}}$ which permits the kidney to excrete all the $\text{K}^+$ that is ingested in a steady state$^8$.

1) The flow rate in the CCD

The flow rate in the CCD is directly proportional to the rate of excretion of osmoles and can be expressed as the urine osmole excretion rate divided by plasma osmolality (urine osmolality $\times$ volume/plasma osmolality) because urine osmolality in the terminal CCD is equal to the plasma osmolality when anti-diuretic hormone (ADH) is present$^8$. While the rate of flow in the CCD is high during a water diuresis, the rate of $\text{K}^+$ excretion need not be elevated because ADH must be present to have high rates of $\text{K}^+$ secretion. The flow rate in the CCD can also be indirectly represented by urine osmolality/creatinine.

2) [K$^+$]$_{\text{CCD}}$

$\text{K}^+$ secretion in the CCD depends on the $\text{K}^+$ channel conductance of the apical membrane (primarily by renal outer medullary $\text{K}^+$ Channel, ROMK) driven by the electrogenic reabsorption of $\text{Na}^+$ (a lumen-negative transepithelial voltage) via epithelial $\text{Na}^+$ channels (ENaC)$^9$. Blood aldosterone and luminal bicarbonate (HCO$_3^-$) are two major factors enhancing $\text{K}^+$ secretion in the CCD$^{10}$. Aldosterone action leads to an increase in the activity of the ENaC and an alkaline luminal pH appears to exert a decrease in the apparent permeability of chloride (Cl$^-$) and/or an increase in open probability of ROMK. There are two ways to generate more negativity in the lumen of the CCD and thus drive $\text{K}^+$ secretion. When $\text{Na}^+$ is reabsorbed faster than Cl$^-$ (fast Na$^+$ disorders) or Cl$^-$ is reabsorbed slower than Na$^+$ (slow Cl$^-$ disorders) (Fig. 1), the lumen of the CCD becomes more negatively charged (electrogenic) and drives $\text{K}^+$ secretion via the ROMK channel. The [K$^+$]$_{\text{CCD}}$ in the CCD can be estimated by calculating the transtubular K$^+$ gradient [TTKG=(urine/plasma [K$^+$])/(urine/plasma osmolality)]. A TTKG greater than 3 in the presence of hypokalemia indicates fast Na$^+$ or slow Cl$^-$ disorders$^{11}$.

Aproach to the genetic causes of hypokalemia

Several acquired extrarenal and renal disorders can have the same findings of hypokalemia as genetic causes. An understanding of the genetic causes of hypokalemia will help determine the molecular defect and avoid inappropriate and cumbersome genetic testing. A detailed history and measurement of blood pressure (BP), $\text{K}^+$ excretion rate, and blood acid-base status can help discriminate between the diverse acquired and genetic causes of hypokalemia. Historical clues such as prior hypokalemia, associated organ abnormalities in family members, use of drugs affecting hypokalemia—diuretics, licorice, and aminoglycosides—onset of age,
and nephrolithiasis or nephrocalcinosis must be carefully obtained. The finding of concomitant hypertension and hypokalemia without the use of diuretics suggest the presence of a mineralocorticoid excess state (MES). A major branch point in hypokalemic pathophysiology is the renal $K^+$ excretion response during hypokalemia. The 24-hour urine and/or spot urine have been used to assess renal $K^+$ excretion rate. We prefer a spot (timed) urine collection prior to therapy as a fast and practical alternative. Four spot urine indices of renal response to hypokalemia have been used: fractional excretion of $K^+$, TTKG, urine $K^+$/creatinine ratio and urine osmolality/creatinine. A 24-hour urine, if collected properly, can provide additional information such as how much $K^+$ is needed to replace the $K^+$ deficit and the state of $K^+$ balance from calculation of $K^+$ input and output. Because $K^+$ deficits usually accompany $HCO_3^-$ or $Cl^-$ loss regardless of the route of $K^+$ loss (gastrointestinal, sweat and renal), either metabolic acidosis or alkalosis is common. In contrast, conditions of intracellular shift usually exhibit relatively normal acid-base balance. Accordingly, the simultaneous assessment of blood acid-base state is also very crucial in patients with hypokalemia. Therefore, the etiology of hypokalemia can simply be divided into two groups: those with a low $K^+$ excretion rate and those with a high $K^+$ excretion rate.

**1. Disorders with a low urine $K^+$ excretion rate**

Disorders in the gastrointestinal tract, excessive sweating and conditions with increased shift of extracellular $K^+$ into cells can lead to a low urine $K^+$ excretion. Generally, an increased shift of extracellular $K^+$ into cells can occur acutely in a number of highly stressful conditions associated with increased catecholamines or hyperinsulinemia via the activation of membrane $Na^+_\text{-}K^+$-ATPase or NHE activity. Barium intoxication and chloroquine overdose cause hypokalemia via the direct closure of cellular membrane $K^+$ channels. One should separate the disorders with hypokalemic periodic paralysis (HPP) due to acute shift of $K^+$ into cells from non-HPP, where there is a large total body deficit of $K^+$. Within the HPP subgroups, the most common are thyrotoxic periodic paralysis (TPP) and sporadic or idiopathic periodic paralysis (SPP) in Asia and familial periodic paralysis (FPP) in Western countries.

**1) Genetic hypokalemia due to increased $K^+$ shift**

**(1) Familial hypokalemia periodic paralysis (FPP)**

It is an autosomal dominant disorder, which is accompanied by muscle weakness or paralysis and occurs more frequently in males, with incomplete penetrance and later onset observed in affected females. Some cases may present as sporadic because of the incomplete penetrance of the disease, mostly in women. Attacks can be induced by rest after exercise, carbohydrate-rich meals, exposure to cold, or the administration of glucose or insulin or glucocorticoid. Acetazolamide, a carbonic anhydrase inhibitor, can reduce the frequency of attacks in FPP with unclear mechanisms. The molecular lesions affect ion channel genes encoding the dihydropyridine-sensitive voltage-gated Ca$^{2+}$ channel $\alpha_1$-subunit (CACNA1S) (FPP type I) and tetrodotoxin-sensitive voltage-gated Na$^+$ channel $\alpha$-subunit (SCN4A) (FPP type II) of skeletal muscle. The Na$^+$ channel $\alpha$-subunit shares primary and secondary structure with the Ca$^{2+}$ channel $\alpha$-subunit including segments spanning the membrane (S1-S6). The S4 segment contains a high density of positively charged amino acids, with every third one being lysine or arginine, and acts as the voltage sensor in voltage-dependent channel activation. To date, five point mutations affecting arginine substitutions in segment S4 of domains II, III and IV (R528G/H, R900S, R1239G/H) of CACNA1S and eleven point mutations in segment S4 of domains I, II and III of SCN4A (R222W, R669H, R672G/H/C/S, R675G/Q/W, R1132Q, R1135H) have been found in patients with FPP. Why mutations in segment S4 of CACNA1S and SCN4A cause episodic hypokalemia remains unclear.

**(2) Andersen-Tawil syndrome**

It is an autosomal-dominant channelopathy resulting in episodic attacks of muscle weakness (mainly acute
hypokalemia, but can be normo- or hyperkalemia), cardiac arrhythmia (ventricular arrhythmias and QT prolongation) and distinctive physical features.\(^{19}\) Mutations in the gene (KCNJ2) encoding a pore-forming subunit of the inward rectifier K\(^+\) channel protein, Kir2.1, which is expressed in skeletal muscles and heart, lead to this syndrome.\(^{19}\) The majority of patients with this syndrome have missense mutations that inhibit channel function through a dominant negative effect. Like FPP, some cases may present as sporadic because of the incomplete penetrance of the disease or have de novo mutation. Furthermore, a wide range of phenotypic severity exists, which can make the correct diagnosis difficult. In contrast to FPP, where cardiac arrhythmias provoked by severe hypokalemia during attacks normalize upon recovery, persistent electrocardiogram abnormalities between attacks is likely in this syndrome.\(^{20}\)

2) Genetic hypokalemia where the defect is in the intestinal tract

Congenital chloride-losing diarrhea (CLD) is a rare autosomal recessive disorder characterized by watery diarrhea, hypokalemia and hypochloremic metabolic alkalosis with high fecal content of Cl\(^-\) (>90 mEq/L).\(^{21}\) It is caused by an inactivating mutation in the downregulated in adenoma (DRA) gene encoding a Cl\(^-\)/OH\(^-\) (HCO\(_3\)\(^-\)) exchanger expressed in the apical membranes of the colon and ileum with functional similarities with the anion exchange proteins.\(^{22}\) Like acquired intestinal inflammation with reduced DRA expression, mutated DRA causes the reabsorption of Cl\(^-\) and secretion of HCO\(_3\)\(^-\) to fall. Proton-pump inhibition of gastric chloride secretion is helpful in diminishing the delivery of Cl\(^-\) to the colon and in lessening the degree of hypokalemia and metabolic alkalosis in CLD.

3) Genetic hypokalemia where the defect is in exocrine glands

Cystic fibrosis (CF) is an exocrine disease affecting multiple organ systems. The defect in the cystic fibrosis transmembrane regulator (CFTR), acting primarily as a Cl\(^-\) channel, is associated with CF.\(^{23}\) Hypokalemia is not uncommon in patients with CF, especially in tropical or subtropical areas. Defective chloride reabsorption by the dysfunctional CFTR in the sweat ducts of CF patients is responsible for excessive Cl\(^-\) and Na\(^+\) loss in sweat. ECF volume depletion with secondary hyperaldosteronism not only causes Na\(^+\) reabsorption and K\(^+\) secretion in the CCD, but may also augment K\(^+\) secretion in sweat ducts and thereby contribute to the hypokalemia.

2. Disorders with a high urine K\(^+\) excretion rate

Hypokalemia due to renal K\(^+\) wasting is chronic and usually related to disorders with either increased flow rate to the CCD or increased K\(^+\) in the CCD (fast Na\(^+\) or slow Cl\(^-\)).

1) Increased urine flow rate to CCD

Flow rate to the CCD is enhanced when osmole excretion rate is increased. Increased osmole excretion rate can be caused by increased excretion of electrolytes (diuretics or tubular defects) or non-electrolytes (mannitol, glucose, urea).

2) Increased [K\(^+\)] in the CCD

1) Fast Na\(^+\) disorders

Because Na\(^+\) reabsorption in the CCD is augmented, ECF volume is usually expanded and thus BP is high, as in states of mineralocorticoid excess.\(^{3}\) In this setting, measurement of plasma renin activity, aldosterone and cortisol concentration help to narrow the differential diagnosis of fast Na\(^+\) disorders (Fig. 2). Plasma renin activity and aldosterone levels are high in patients with renin-secreting tumor, renal vascular stenosis, malignant hypertension, and pheochromocytoma. High plasma aldosterone levels but low plasma renin activity indicates primary hyperaldosteronism which can be caused by bilateral adrenal hyperplasia, adrenal adenoma/carcinoma, and glucocorticoid-remediable aldosteronism (GRA). In
contrast, low plasma aldosterone level and renin activity represent pseudohyperaldosteronism. Based on the plasma cortisol concentration, three subgroups can be readily divided. Patients with high plasma cortisol concentrations may have ectopic adrenocorticotropic hormone (ACTH), Cushing’s syndrome or exogenous hydrocortisone administration. Low plasma cortisol concentration suggests the diagnosis of congenital adrenal hyperplasia (CAH) due to either 11β-hydroxylase or 17α-hydroxylase deficiencies (11β-OHD and 17α-OHD). A normal plasma cortisol level can be found in 11-deoxycorticosterone (DOC) producing adenoma, Liddle’s syndrome, apparent mineralocorticoid excess, and chronic licorice ingestion.

a. Genetic hypokalemia associated with mineralocorticoid excess state

The mineralocorticoid receptor (MR), the major regulator of ENaC activity, is normally activated by aldosterone. Genetic mutations causing abnormalities in aldosterone secretion or production of other steroids that activate the MR will lead to hypertension and hypokalemia.

i. Glucocorticoid-remediable aldosteronism

GRA is an autosomal dominant form of hypertension caused by a chimeric gene duplication arising from unequal crossing over between two closely related genes involved in adrenal steroid biosynthesis. These two genes are 11β-hydroxylase (CYP11B1) encoding aldosterone synthase for aldosterone biosynthesis in the adrenal glomerulosa regulated by angiotensin II and aldosterone synthase (CYP11B2) encoding 11β-hydroxylase for cortisol biosynthesis in the adrenal fasciculata regulated by ACTH. The unequal crossover between CYP11B1 and CYP11B2 genes results in CYP11B2 that allows aldosterone synthesis to be under the control of regulatory promoter sequences of CYP11B1 by ACTH rather than its normal regulator, angiotensin II. Aldosterone secretion thus becomes linked to cortisol secretion, leading to clinical and

laboratory features of primary aldosteronism. Exogenous 
glucocorticoids diminish the ACTH-regulated chimeric 
genes, in turn suppressing the secretion of aldosterone, 
leading to reversal of the features of GRA.

ii. CAH due to 11β-OHD and 17α-OHD

Two forms of CAH have hypertension and hypokalemia 
accompanying a characteristic phenotype with abnormal 
androgen production and sexual differentiation. They 
are 11β-OHD and 17α-OHD caused by CYP11B1 and 
CYP17 mutations, respectively. Increased ACTH levels in 
11β-OHD leads to elevation of 11-deoxycortisol (compound 
S) and DOC, causing MES. Cortisol precursors are 
diverted through the 17,20-lyase pathway and this results 
in hyperandrogenemia, causing acne, hyperpigmentation, 
and an enlarged phallus in males and prenatal virilization 
of genitalia in the female newborn. 17α-OHD has both 
defective 17α-hydroxylase and 17,20-lyase activities of 
the 17α-hydroxylase essential for the synthesis of cortisol 
gonadal hormones. Lack of 17,20-lyase activity in 
17α-OHD prevents androgen synthesis and results in under-
virilization in males and failure of spontaneous pubertal 
development in females. Steroid therapy ameliorates the 
hypertension and hypokalemia as well as the associated 
signs and symptoms.

iii. Liddle’s syndrome

It is characterized by autosomal dominant transmission 
of early onset hypertension associated with hypokalemia, 
metabolic alkalosis, suppressed plasma renin activity, and 
extremely low plasma aldosterone levels. This disease 
is caused by mutations in either the β or the γ subunit of 
ENaC that delete or alter their cytoplasmic C termini. 
The mutated ENaC are not internalized (clathrin-coated 
pits pathway) or degraded (Nedd4 pathway), and instead 
remain in an activated form on the cell surface. The 
channel is amiloride and triamterene sensitive provided 
their concentrations are high enough in luminal fluid, 
explaining the efficacy of these K⁺-sparking diuretics in 
the syndrome.

iv. Apparent mineralocorticoid excess (AME)

AME is a rare but potentially fatal autosomal re-
cessive form of hypertension and hypokalemic meta-
bulic acidosis associated with hyporeninemia and 
hypoaldosteronemia and an abnormal ratio of urinary 
metabolites of cortisol with a high tetrahydrocortisol:tet 
hydrocortisone (THF:THE) ratio. AME is caused by 
mutations in the gene (HSD11B2) encoding renal-specific 
11β-hydroxysteroid dehydrogenase type 2 (11β-HSD2). 
11β-HSD2 is responsible for converting cortisol to 
cortisone in the principal cells of distal tubules and crucial 
for protecting the MR from being occupied by cortisol. 
The hallmark features in AME resemble those in licorice 
ingestion because licorice contains glycyrrhetinic acid, 
which inhibits 11β-HSD2.

(2) Slow Cl⁻ disorders

Because Cl⁻ reabsorption in the CCD is diminished, ECF 
volume is usually contracted and thus BP is relatively low 
to normal. Because extracellular K⁺ deficit is often accompanied 
by ECF HCO₃⁻ or Cl⁻ loss, slow Cl⁻ disorders can have 
either hyperchloremic metabolic acidosis or hypochloremic 
metabolic alkalosis.

a. Hypochloremic metabolic alkalosis

Metabolic alkalosis is diagnostically useful in patients 
with severe KCl depletion. An assessment of urine Na⁺ 
and Cl⁻ may reveal the basis for renal tubular electrolyte 
disorders and distinguish it from non-renal Na⁺ loss 
(Fig. 2). Low excretion of Na⁺ and Cl⁻ indicate remote 
vomiting, remote or yesterday’s diuretics, Cl⁻-losing 
diarrhea (e.g. congenital chloridorrhea), or excessive 
sweating. Low urine Na⁺, but high Cl⁻ excretion, in the 
presence of hypokalemia and metabolic alkalosis suggests 
laxative abuse or some chronic diarrhea states with chronic 
stimulation of renal NH₄⁺ excretion. Conditions of high 
Na⁺ excretion, but low Cl⁻, suggests the presence of an 
anion that is not reabsorbed. If the urine is alkaline (pH >7), 
vomiting and/or ingestion of bases are the likely 
causes. If the urine is not alkaline, intake or generation
of anions that are poorly reabsorbed by the kidney is likely. A high urine Na\(^+\) and Cl\(^-\) excretion is indicative of the recent use of diuretics, intrinsic renal disease, or lack of signaling to stimulate NaCl reabsorption. Inherited or acquired renal tubular disorders such as Gitelman’s syndrome (GS), Bartter’s syndrome (BS), and related drug-induced toxic disorders, such as from aminoglycosides, cisplatin, diuretics, and foscarin, are often the diagnoses.

The evaluation of urine divalent Mg\(^{2+}\) and Ca\(^{2+}\) excretion helps localize the exact tubular defect. High urine Ca\(^{2+}\) and Mg\(^{2+}\) excretion is universally present in lesions of the loop of Henle (LOH) whereas low urine Ca\(^{2+}\) and high Mg\(^{2+}\) excretion is invariably found in lesions of the DCT.

i. Bartter’s syndrome (BS) and Gitelman’s syndrome (GS) BS and GS are autosomal recessive renal tubular disor-

orders characterized by chronic hypokalemia with renal K⁺ wasting, metabolic alkalosis, renal salt wasting with low to normal BP and secondary hyperreninemia and hyperaldosteronism. BS results from defective reabsorption of NaCl in the LOH whereas GS is secondary to defective reabsorption of NaCl in the DCT. At the molecular level, GS is mostly due to inactivating mutations in the SLC12A3 gene, which encodes the thiazide-sensitive Na⁺/Cl⁻ cotransporter (NCC) on the apical membrane of the DCT. The five subtypes of BS arise from inactivation mutations in genes encoding the Na⁺/K⁺/2Cl⁻ cotransporter (NKCC2), K⁺ channel (ROMK), kidney-specific Cl⁻ channel (CLCNKB), barttin (BSND) and calcium-sensing receptors (CaSR). The five subtypes of BS arise from inactivation mutations in genes encoding the Na⁺/K⁺/2Cl⁻ cotransporter (NKCC2), K⁺ channel (ROMK), kidney-specific Cl⁻ channel (CLCNKB), barttin (BSND) and calcium-sensing receptors (CaSR). (Table 1, Fig. 3). Recently, a complex syndrome consisting of a combination of epilepsy, ataxia, sensorineural deafness and renal tubulopathy featuring laboratory findings of GS (EAST or SeSAME syndrome) has been described, due to inactivating mutations in the gene encoding Kir4.1, which is also highly expressed in the basolateral membrane of the DCT. Loss of Kir4.1 function may reduce Na⁺,K⁺-ATPase and accumulate intracellular Na⁺, leading to reduced salt reabsorption in the DCT, similar to GS.

A maternal history of polyhydramnios, age of onset, neurologic symptoms, deafness, presence of nephrocalcinosis or renal stones, and serum divalent concentration with their urine excretion rates help distinguish among the subtypes of BS and GS. Because Cl⁻ channels are expressed in both the basolateral membrane of LOH and DCT, some patients with classical BS may have clinical profiles similar to that of GS. Unlike BS, non-steroid anti-inflammatory drugs (NSAIDs) are usually not effective in patients with GS due to the relatively normal urinary prostaglandin E2 excretion.

The degree of chronic hypokalemia has been reported to be milder in GS than BS. In fact, profound hypokalemia is not uncommon in patients with GS and is also difficult to correct even with high K⁺ supplementation and the use of K⁺-sparing agents. Besides ROMK channels, Ca²⁺-activated maxi-K⁺ channels (BKCa), a large-conductance channel stimulated by increased distal renal tubule flow, play an important role in K⁺ secretion when the flow rate is high.

Fig. 3. Transport proteins in the thick ascending limb (TAL) of loop of Henle (LOH) (left panel) and distal convoluted tubule (DCT) (right panel) affected by gene mutations. Mutations that inactivate Na⁺/K⁺/2Cl⁻ cotransporter (NKCC2) or renal outer medullary K⁺ channel (ROMK) lead to antenatal Bartter syndrome/hyperprostaglandin E syndrome (aBS/HPS) (BS type I and II) and mutations inactivating CIC-Kb cause classic Bartter syndrome (cBS) (BS type III). Mutations in barttin (chloride channel β-subunit) cause antenatal BS with sensorineural deafness (BSND) (BS type IV). Mutations that activate the calcium-sensing receptors (CaSR) occur in patients with autosomal dominant hypoparathyroidism (ADH) (BS type V). Mutations inactivating Na⁺/Cl⁻ cotransporter (NCC) or basolateral Cl⁻ channel (CIC-Kb) can cause Gitelman’s syndrome (GS). Mutations in Kir4.1 channel cause seizures, sensorineural deafness, ataxia, mental retardation, and electrolyte imbalance (SeSAME) syndrome. ADH, anti-diuretic hormone
to the CCD is increased\(^{39}\). The importance of maxi-K\(^+\) channels in renal K\(^+\) secretion is further supported by the finding that BS patients with ROMK mutations do not have hyperkalemia but hypokalemia. Mutations of ROMK decrease NaCl and flow reabsorption in the LOH and result in increased distal flow delivery to the CCD where flow-stimulated K\(^+\) secretion via maxi-K\(^+\) channels are enhanced despite the loss of functional ROMK\(^{40}\). We have found that both ROMK1 and maxi-K\(^+\) expression were increased in the distal renal tubules of GS-causing knockin mice on normal K\(^+\) diet, suggesting that both channels are involved in renal K\(^+\) wasting in GS (unpublished data). The mice on a high K\(^+\) diet still had hypokalemia, indicating that increased intake was matched by increased excretion. Although ROMK1 expression was unchanged between normal and high K\(^+\) diets, maxi-K\(^+\) was further increased, suggesting that ROMK1 expression had reached a ceiling, but not maxi-K\(^+\) expression, which may also be stimulated by K\(^+\) repletion and aldosterone. Over-expression/activation of maxi-K\(^+\) may be responsible for the persistent hypokalemia in GS patients despite K\(^+\) supplementation (Fig. 4). These findings raise the possibility of maxi-K\(^+\) inhibitors as an alternate therapeutic target in managing chronic refractory hypokalemia.

b. Hyperchloremic metabolic acidosis

Hyperchloremic metabolic acidosis provides an important diagnostic clue for the presence of a pathophysiologic process involving both K\(^+\) depletion and direct or indirect loss of HCO\(_3^-\). Estimating the urine NH\(_4^+\) concentration unveils the basis of metabolic acidosis associated with K\(^+\) depletion\(^{41}\). The excretion of NH\(_4^+\) is low in patients with renal tubular acidosis (RTA), whereas, this excretion is not depressed in simple gastrointestinal loss of NaHCO\(_3\). An indirect estimate of NH\(_4^+\) can be obtained from the urine anion gap (Na\(^++\)+K\(^+-\)Cl\(^-\)) or osmolal gap (measured-calculated urine osmolality)/2. The causes for patients who do not have a low NH\(_4^+\) excretion rate include gastrointestinal loss of HCO\(_3^-\), chronic toluene abuse, treatment of diabetic acidosis with insulin, and ureteral diversion. Positive urine net charge and osmolal gap less than 100 mOsm/kg H\(_2\)O are indicative of low urine NH\(_4^+\) excretion, pointing to the diagnosis of RTA. RTA can be proximal or distal in origin. Intravenous NaHCO\(_3\) loading at a rate of 2-3 mEq/kg/hour can be administered to separate proximal from distal RTA.

---

**Fig. 4.** Mechanisms for persistent hypokalemia in Gitelman’s syndrome (GS). Enhanced epithelial Na\(^+\) channels (ENaC), renal outer medullary K\(^+\) channel (ROMK)1 and Maxi-K expression leads to hypokalemia (middle). High K\(^+\) supplement stimulates more accentuated maxi-K expression, accounting for persistent hypokalemia (left). DCT, distal convoluted tubule; CNT, cortical connecting tubules; CCD, cortical collecting duct.
• Inherited isolated proximal RTA

Most of the filtered HCO₃⁻ is reabsorbed in the proximal convoluted tubules (PCT) as a result of H⁺ secretion via the electroneutral Na⁺/H⁺ exchanger 3 (NHE3) in the luminal membrane and HCO₃⁻ exit via the electrogenic Na⁺/HCO₃⁻ cotransporter (NBC1) in the basolateral membrane. Defects in NHE3 or NBC1 can theoretically reduce the reabsorption of filtered HCO₃⁻ and cause proximal RTA (pRTA). Mutations in the NHE3 gene have not been identified in patients with proximal RTA to date. On the other hand, mutations in the NBC1 gene (SLC4A4) have been reported in patients with autosomal recessive isolated proximal RTA. Because NBC1 is also expressed in the ocular tissues and brain, patients with inactivating mutations in NBC1 have ocular abnormalities (glaucoma, band keratopathy, and cataracts) as well as calcifications of the basal ganglia. Of note, hypokalemia is almost always present and can be very severe when a high dose of oral NaHCO₃ is given.

• Inherited distal RTA

Apical H⁺-ATPase pump and basolateral Cl⁻/HCO₃⁻ exchanger (anion exchanger 1, AE1) in the late distal tubule (predominantly in α-intercalated cells) participate in the excretion of NH₄⁺, which adds new HCO₃⁻ to the body. Genes encoding two H⁺-ATPase subunits specific to intercalated cells have been identified as ATP6V1B1 and ATP6V0A4. Because ATP6V1B1 is also expressed in endolymphatic sac epithelia, mutations in ATP6V1B1 cause distal RTA with sensorineural hearing loss, whereas, distal RTA with preserved hearing is caused by mutations in ATP6V0A4. AE1 (SLC4A1) is also present in erythrocytes and inactivating mutation in AE1 causes distal RTA and possible anemia. Hypokalemia in hereditary distal RTA is often severe. First, low distal H⁺ secretion reduces luminal HCO₃⁻ reabsorption and this leads to bicarbonaturia. Second, the mistargeting of AE1 due to the second mutation in AE1 leads to HCO₃⁻ secretion. Reminiscent of alkalinized intercalated cells in Sjögren’s syndrome with distal RTA, high luminal HCO₃⁻ may lead to augmented K⁺ secretion and hypokalemia.

• Inherited proximal and distal RTA

Carbonic anhydrase II (CA₂⁺) is known to be expressed in both proximal and distal nephron segments and participates in H⁺ secretion in both the proximal and distal nephron; CA₂⁺ is also expressed in brain and osteoclasts. Mutations in CA₂⁺ can lead to an autosomal recessive proximal and distal RTA with osteopetrosis and cerebral calcification. The bone thinning effect of the coexistent metabolic acidosis in CA₂⁺ deficiency may protect the osteopetrotic bones from the excessive thickening generated by osteoclast dysfunction.

Therapeutic strategy in genetic hypokalemia

Genetically engineered mice are often used as animal models of human diseases and are vital tools in investigating molecular pathogenesis of disease and developing and testing novel therapies. It is worthy to emphasize that knock-out mice typically represent null mutations and could be used to study only the effects of the loss of a gene, not a specific mutation. Knockin strategies, where homologous recombination in embryonic stem (ES) cells is used to replace the endogenous gene with a mutant variant without any other disruption of the gene, can be used to address the effects of specific sequence changes on gene and protein function. Therefore, knockin mice accurately represent human diseases caused by specific mutations, such as missense, nonsense, or deletion mutations. More importantly, mutation-specific approaches according to the different classes of mutations are currently under investigation to provide a new alternative therapy in genetic disorders. We believe that the application of these diseases-causing knock-in mice may address more specific questions regarding the pathogenesis and new directions in rescue therapies; for instance, rational application of aminoglycosides or premature termination codon (PTC) 124 for nonsense mutations and pharmacologic chaperones for missense mutations.
Conclusion

Apart from a detailed history and careful physical examination, the measurement of urine K⁺ excretion rate by spot and/or 24 hour urine, and assessment of blood acid-base status helps discriminate the causes of hypokalemia. Once the clinical diagnosis suggests a likely molecular basis for the disorder, genetic analysis may prove the diagnosis. Genetic causes of hypokalemia are shown in Table 1. Creation and investigation of disease-causing knockin mice as a model of genetic hypokalemia will not only provide a much better understanding of the underlying mechanisms; but also set the stage for the development of novel therapies in the future.
