Stress-induced cardiomyopathy (SICM) presenting as an acute myocardial dysfunction is characterized by transient left ventricular wall motion abnormality, which has been known to be associated with excessive catecholamine production caused due to various types of stress. Sympathetic hyperactivity is common during the perioperative period, and reports of SICM occurring during this period have actually increased. We present a case of SICM following negative pressure pulmonary edema due to upper airway obstruction during emergence from anesthesia. Excessive catecholamine release in response to respiratory difficulty could have been the underlying inciting factor. (Korean J Anesthesiol 2012; 62: 79-82)

Key Words: Negative pressure pulmonary edema, Stress-induced cardiomyopathy.

Stress-induced cardiomyopathy (SICM) presenting as an acute myocardial dysfunction is characterized by transient left ventricular wall motion abnormality, which has been known to be associated with excessive catecholamine production that is precipitated by physical or emotional stress, but its pathophysiology has still not been fully understood [1]. Various procedures including surgery are also the principal relevant factors. Sympathetic hyperactivity is common during the perioperative period, and reports of SICM occurring during this period have actually increased [2-12]. Therefore anesthesiologists should pay attention to this clinical syndrome,

however the exact pathophysiologic mechanism or prevalence is not well known.

We present a case of SICM following negative pressure pulmonary edema (NPPE) due to upper airway obstruction during emergence from anesthesia.

Case Report

A 56-year-old man, 172 cm in height and 85 kg in weight, was scheduled for tonsillectomy to rule out tonsillar cancer. He had a medical history of hypertension and non-insulin dependent

Received: April 22, 2011. Revised: 1st, June 3, 2011; 2nd, June 22, 2011. Accepted: June 29, 2011.

diabetes since the last 5 years and he was taking the following medications; Valsartan (Diovan[®]), Amlodipine + Atorvastatin (Caduet[®]), Sulodexide (Vessel Due F[®]), Fenofibrate (Lipidil Supra[®]), Aspirin (Astrix[®]), Pregabalin (Lyrica[®]) and Glibenclamide + Metformin (Gluriad[®]). During endocrinology clinic follow-up, chest X-ray showed three small well-defined nodular opacities in the left lower lung field and high-resolution computed tomography (CT) of chest showed suspicious metastatic nodules in lower lobes of both lungs and a small nodular lesion with high attenuation in the ampulla of Vater. To detect the original cancer lesion, esophagogastroduodenoscopy was performed, which showed no specific findings except gastric erosion and duodenal ulcer. In addition, abdominal ultrasound, colonoscopy, and positron emission tomography-computed tomography were performed, but the original cancer lesion could not be detected. However, chest CT for CT-guided needle aspiration biopsy showed lymph node enlargement in the left oropharynx which could be the suspected primary focus, and hence a tonsillectomy was scheduled.

Preoperative laboratory tests were all within normal limits. The electrocardiogram (EKG) showed nonspecific ST abnormality with normal sinus rhythm at a rate of 93 beats/min and a transthoracic echocardiogram showed normal sized cardiac chambers and normal global left ventricular (LV) systolic function with an ejection fraction (EF) of 58%. A treadmill exercise stress test showed equivocal changes in stage 4. His functional capacity was more than 4 METs and he had no specific symptoms, but he had a lot of concerns about the progress and prognosis of pulmonary nodules that might be cancer metastasis. He denied any symptoms of chest pain or dyspnea preoperatively.

Fig. 1. Immediate postoperative chest AP radiograph shows increased opacity in bilateral perihilar areas.

The patient was premedicated with intravenous glycopyrrolate 0.2 mg. Before anesthesia induction, his blood pressure was 165/97 mmHg, heart rate (HR) was 76 beats/min and peripheral oxygen saturation (SpO₂) was 97%. Anesthesia was induced with propofol 120 mg and continuous infusion of remifentanyl. After neuromuscular block was achieved with 50 mg rocuronium, he was intubated with an 8.0 mm inner diameter endotracheal tube. Anesthesia was maintained with sevoflurane in 60% oxygen with air and systolic blood pressure was maintained at 100–160 mmHg, diastolic blood pressure at 65–100 mmHg, HR at 80–90 beats/min, and SpO₂ above 98%. Tonsillectomy was performed and the surgery lasted for 25 minutes. At the conclusion of tonsillectomy, suction catheter was applied to the endotracheal tube and oral cavity, and there was a little secretion or blood. During emergence from anesthesia, 100% oxygen was given and when the patient started to breathe spontaneously, muscle relaxant was reversed with neostigmine 1.0 mg and glycopyrrolate 0.2 mg. Extubation was performed after he could obey verbal commands such as opening the eyes. Immediately after extubation, the patient had difficulty in breathing and developed inspiratory stridor suggesting upper airway obstruction. An oral airway was inserted and 100% oxygen was administered via a face mask during spontaneous assisted ventilation. However, he continued to have difficulty in breathing and SpO₂ decreased to 77%, blood pressure was 164/101 mmHg, and HR was 125 beats/min. Reintubation was performed approximately 5 minutes after extubation. After reintubation, a large amount of pinkish, frothy secretion was suctioned from the endotracheal tube, arterial blood gas analysis (ABGA) showed a pH of 7.24, arterial carbon dioxide tension (PaCO₂) of 55.6 mmHg, arterial oxygen tension (PaO₂) of 47.9 mmHg and arterial oxygen saturation (SaO₂) of 74.1% at an FiO₂ of 1.0 and chest X-ray showed increased opacity in bilateral perihilar areas (Fig. 1), consistent with NPPE. With endotracheal suctioning and administration of furosemide 10 mg, ABGA showed a pH of 7.23, PaCO₂ of 53.7 mmHg, PaO₂ of 75.7 mmHg and SaO₂ of 91.9% at an FiO₂ of 0.8 and positive end-expiratory pressure (PEEP) of 10 cmH₂O. The patient was transferred to the intensive care unit (ICU).

After admission to ICU, mechanical ventilation was maintained at an FiO₂ of 0.8 and PEEP of 12 cmH₂O, and SpO₂ increased to 96%. Because blood pressure was 77/51 mmHg and HR 106 beats/min, a dopamine infusion was initiated. However, blood pressure did not increase, and a norepinephrine infusion was initiated, blood pressure was maintained at around 120/70 mmHg.

After approximately 5 hours of reintubation, EKG changes were seen on the bedside monitor. The 12-lead EKG revealed ST-segment elevation in leads V₂₋₄ and T-wave inversion in leads I, aVL, V₂₋₆ (Fig. 2). Cardiac biomarker assay showed an increased

CK-MB level of 8.8 ug/L and an increased troponin I level of 2.03 ug/L. Bedside echocardiography and emergency coronary angiography (CAG) were performed. The echocardiogram revealed akinesia of the left ventricular wall from mid to apex causing apical ballooning (Fig. 3) and a reduced EF of 47%. The CAG showed minimal luminal narrowing and apical ballooning was shown on the left ventriculogram. The patient was diagnosed with SICM.

On postoperative day (POD) 1, ABGA at an FiO_2 of 0.4 and PEEP of 10 cmH_2O showed a pH of 7.39, PaCO_2 of 42.5 mmHg, PaO_2 of 132.9 mmHg and SaO_2 of 99.0%. Although chest X-ray appeared to have improved, blood pressure was 82/56 mmHg and HR was 114 beats/min, and a dobutamine infusion was added.

On POD 2, both norepinephrine and dopamine infusions were tapered off. On POD 4, chest X-ray showed more improvement, he did not have difficulty in spontaneous breathing and ABGA at an FiO_2 of 0.4 and PEEP of 5 cmH_2O showed a pH of 7.45, PaCO_2 of 37.9 mmHg, PaO_2 of 106.9 mmHg and SaO_2 of 99.8%, and hence he has weaned from mechanical ventilation. On POD 5, dobutamine infusion was tapered off, a follow-up echocardiogram revealed no regional wall motion abnormality with an EF of 60%, and he was transferred to the general ward and was discharged on POD 8 without any complications.

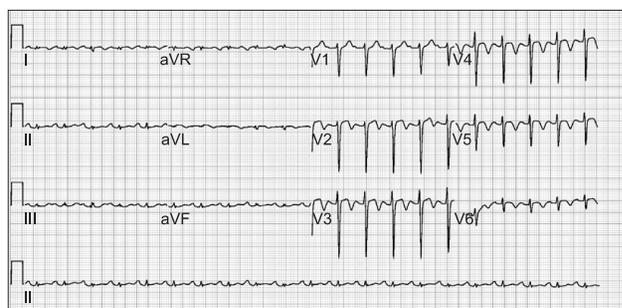

Fig. 2. Postoperative electrocardiogram shows ST segment elevation in leads V_{2-4} and T-wave inversion in leads I, aVL, V_{2-6} .

Discussion

Since SICM was first described as Takotsubo-type cardiomyopathy by Sato et al. in 1990 [13], it has been referred to by various names according to the characteristic clinical features [1]. The occurrence of transient left ventricular wall motion abnormality, the so-called apical ballooning, in the absence of epicardial coronary artery obstruction, is a unique clinical feature, but recently various cases presenting other patterns of wall motion abnormality have been reported. Bybee and Prasad [14] proposed the following diagnostic criteria: 1) transient LV wall motion abnormalities involving the apical and/or midventricular segments with wall motion abnormalities extending beyond a single epicardial coronary distribution, 2) the absence of obstructive epicardial coronary artery disease or angiographic evidence of acute plaque rupture that could be responsible for the observed wall motion abnormality, 3) troponin elevation or new EKG abnormalities such as transient ST segment elevation and/or diffuse T-wave inversions. However, recently some case reports have described that some patients seemed to have SICM, but their clinical features did not correspond to the above mentioned criteria, and therefore a new diagnostic approach is needed.

The diagnosis of SICM in this patient was made on the basis of the above mentioned typical clinical, EKG, echocardiographic, and CAG features, which corresponded to the typical diagnostic criteria, and the clinical course also corresponded with that of SICM. It is unique in this case that SICM was associated with NPPE due to upper airway obstruction during emergence from anesthesia. Although it is not certain whether NPPE due to upper airway obstruction precipitated SICM or both NPPE and SICM occurred independently and exacerbated the clinical features, it is presumed that excessive catecholamine production due to hypoxia was related to the occurrence of SICM. Also, we could not exclude the possibility that emotional stress caused due to the diagnosis of cancer promoted its occurrence. There is no clear explanation for the individual differences in susceptibility to SICM in spite of a

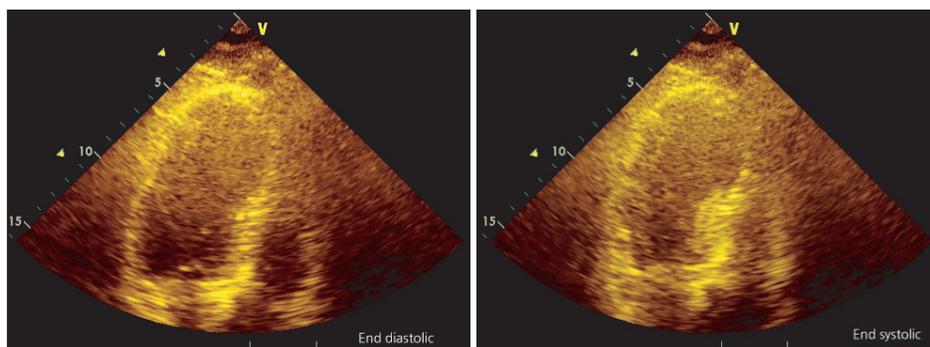

Fig. 3. Transthoracic echocardiography shows left ventricular dysfunction with apical ballooning resembling the octopus trap (takotsubo).

similar degree of stress or precipitating factors.

When considering the differential diagnosis of acute onset postoperative pulmonary edema, we should take into account both cardiogenic and noncardiogenic pulmonary edema preceded by upper airway obstruction (NPPE), acute lung injury, anaphylaxis, fluid maldistribution, or severe central nervous system trauma (neurogenic pulmonary edema) [15]. The clinical features of this case were most consistent with NPPE due to upper airway obstruction as the most likely cause. Upper airway obstruction leading to NPPE has been reported in the events that include laryngospasm, endotracheal tube occlusion, foreign body aspiration, oropharyngeal surgery or residual curarization [15]. Although according to the clinical features, laryngospasm after extubation is the most likely event related with upper airway obstruction in this case, the possibility of residual curarization cannot be excluded because the duration of anesthesia was relatively short and extubation was performed without confirmation of recovery of neuromuscular function.

There are no uniformly accepted treatment strategies for SICM. The patients with SICM generally might receive supportive management for heart failure and there are some considerations regarding the use of beta adrenergic blockade or inotropes. As with this case, most patients of SICM usually recover fully without complications, but serious complications might occur.

Since during the perioperative period, the emotional or physical stress increases and the patient could be susceptible to SICM, anesthesiologists should become adept at diagnosing SICM and managing these patients properly. Although it is unclear how to manage the patients who have a history of SICM and need to undergo surgery, it would be helpful to try to suppress the production of catecholamines during the perioperative period. However, further research is needed to prevent recurrence of SICM or its management.
