It was presented at the 5th Annual Meeting of the Korean Society of Transplantation Anesthesiologists, May 2018, Kyungpook National University Chilgok Hospital, Daegu, Korea.

Monitoring cerebral oxygenation using a near infrared spectroscopy (NIRS) device is useful for estimating cerebral hypoperfusion and is available during liver transplantation (LT). However, high serum bilirubin concentration can interfere with NIRS because bilirubin absorbs near infrared light. We report a patient who underwent LT with a diagnosis of vanishing bile duct syndrome, whose regional cerebral oxygen saturation (rSO_2) remained below 15% even with alert mental status and SpO_2 value of 99%. The rSO_2 values were almost fixed at the lowest measurable level throughout the intra- and postoperative period. We report a case of erroneously low rSO_2 values during the perioperative period in a liver transplant recipient which might be attributable to skin pigmentation rather than higher serum bilirubin concentration.

Keywords: Bilirubin; Brain hypoxia; Hyperbilirubinemia; Liver transplantation; Near-infrared spectroscopy; Oxymetry.

In healthy people, cerebral blood flow (CBF) is maintained steadily as long as the mean arterial pressure (MAP) and partial arterial CO_2 pressure ($PaCO_2$) are within a certain range. The autoregulation of CBF is often impaired in patients with acute or chronic liver failure. In these patients, a change in MAP or $PaCO_2$ will elicit either seriously increased or reduced CBF [1]. Factors likely to affect CBF or cerebral oxygenation include hemodynamic fluctuation, bleeding, and reperfusion syndrome during LT. However, monitoring methods for evaluating cerebral function such as cerebral perfusion pressure, jugular venous oximetry, and intracranial pressure are

somewhat invasive and can lead to severe complications in patients with impaired hemostasis [2,3].

Near-infrared spectroscopy (NIRS) allows non-invasive and real time continuous monitoring of regional cerebral oxygen saturation (rSO_2) [4]. Monitoring cerebral oxygenation using a NIRS device is useful for estimating cerebral hypoperfusion during LT [2,5]. Unfortunately, high serum bilirubin concentration can interfere with NIRS because the bilirubin absorbs near infrared light. Therefore readings may be incorrect in patients with high serum bilirubin. Despite this limitation, it is used clinically as it reflects important trends

in most patients [2,6]. We report a patient who underwent LT with a diagnosis of vanishing bile duct syndrome whose rSO_2 remained below 15% even with alert mental status. We could not observe even the trend of rSO_2 values throughout the LT. This state remained even after bilirubin decreased.

CASE REPORT

A 79-year-old, 163 cm, 56 kg, and dark skin-colored male was admitted for deceased donor LT due to vanishing bile duct syndrome. His past medical history consisted of hypertension diagnosed 10 years previously. Six months earlier, he suffered from nausea and right upper quadrant abdominal pain, and was diagnosed with acute cholecystitis. At that time, his total bilirubin value was 13.28 mg/dl and it remained in the range 10–20 mg/dl in spite of several interventions including endoscopic retrograde bile drainage. His final diagnosis was vanishing bile duct syndrome and LT was recommended.

Preoperative laboratory values were as follows: total bilirubin 20.7 mg/dl, prothrombin time (international normalized ratio) 1.9, and hemoglobin 8.9 g/dl. When he entered the operating room, he was alert and was capable of ordinary conversation with the medical staff.

Anesthesia was induced with intravenous propofol 70 mg and rocuronium 50 mg. Maintenance of anesthesia was achieved with desflurane, 50% oxygen/air mixture (total flow

3 L/min), continuous remifentanyl (target controlled infusion dose 0–3 ng/ml), and continuous rocuronium infusion (5 μ g/kg/min). Right radial and femoral artery were cannulated. An advanced venous access catheter (AVA, Edwards Lifesciences, USA) and 7 Fr triple lumen catheter (Arrow guard blue, Arrow international, USA) were inserted into the right internal jugular vein. A pulmonary artery catheter (Swan-Ganz CCombo V, Edwards Lifesciences, USA) was inserted via AVA catheter for cardiac output monitoring. Cerebral oximeter (INVOS 5100c, Medtronic, USA) and BIS (Covidien, USA) were also monitored. The rSO_2 values before induction of anesthesia were 15% on both sides when the SpO_2 value was 99% (Fig. 1).

Total anesthesia time was 340 minutes and all patient monitoring data was recorded in vital recorder program [7]. No remarkable events occurred. MAP was well maintained above 70 mmHg with continuous norepinephrine infusion (0.1–0.3 μ g/kg/min). Hemoglobin value was above 7.8 g/dl throughout the operation. Total crystalloid 2,750 ml, colloid (albumin) 750 ml, and salvaged blood by cell saver machine (AUTOLOG®, Medtronic, USA) 89 ml were infused. No blood products were administered during the operation. The rSO_2 values did not change on the left side, but a slight elevation from 15 to 30% was observed on the right side before portal vein reperfusion (Fig. 2).

The patient was transferred to surgical intensive care unit for postoperative recovery. The rSO_2 was not monitored when the patient was in the intensive care unit. For further evaluation of the possible cause of abnormally low rSO_2 values during surgery, we visited the patient three days after operation when his total bilirubin level was decreased to 9.82 mg/dl. He was alert, responded correctly to our questions about his body condition, and his vital signs were stable; blood pres-

sure 141/63 (mean, 91) mmHg, and heart rate 53 beats/min. Hemoglobin level was 7.5 g/dl. When we monitored NIRS again, the rSO₂ values were still recorded as 15% in both sides. He was discharged without any complication on postoperative day 21.

DISCUSSION

Vanishing bile duct syndrome is a group of disorders which result in progressive destruction and 'vanishing' of intrahepatic bile ducts (ductopenia). Multiple etiologies including autoimmune, toxins, genetic abnormalities, infections, and neoplasms can lead to this disorder. Ductopenia is a pathologic term which refers to a loss of intrahepatic bile ducts, and eventually leads to cholestasis [8]. The specific cause of the disease in this current patient was not clear. His total bilirubin level was persistently high (10–20 ml/dl) about 6 months before LT. This long lasting hyperbilirubinemia seems to have caused significant skin pigmentation that led to the measurement error in NIRS and did not immediately disappear even after bilirubin concentration decreased. Under these circumstances, NIRS provides unreliable values in patients with vanishing bile duct syndrome during LT and this problem persists in spite of lowered bilirubin concentration after surgery. It indicates a critical limitation of NIRS.

According to the manufacturer's manual, the measurable range of rSO₂ reading was 15–95% (updated every 5–6 seconds) in the INVOS 5100c. Therefore, if rSO₂ values were < 15%, the machine displayed a result of 15%. The rSO₂ values of our patient were 15% on both sides before anesthesia induction. It was hard to believe that these rSO₂ values reflected the real cerebral oxygen status, because he was alert and was capable of conducting ordinary conversation at that time.

The INVOS system uses dual wavelengths of near infrared light that are absorbed by oxy/deoxy hemoglobin (730 and 810 nm). It is reported that the absorptivity of near infrared light by oxy/deoxy hemoglobin is well separated at 730 nm wavelength, but is similar at 810 nm. Unfortunately, conjugated bilirubin has a peak absorptivity at 730 nm. Bilirubin can be deposited in all tissue layers which can affect the capacity for assessing cerebral oxygenation by NIRS in patients with icterus [6,9].

Song et al. [2] reported that high total bilirubin and low

hemoglobin are independent associated factors for low rSO₂ values in patients with liver disease. They suggested that low rSO₂ values in patients with icterus may be an artifact rather than true ischemia [2]. Madsen et al. [6] investigated 48 patients who underwent LT and reported that rSO₂ was lowered but the internal jugular O₂ saturation was not affected. They concluded that despite underestimating rSO₂, the directional changes in rSO₂ seemed to be observable even in patients with high bilirubin levels [6].

In the current case, we assume that rSO₂ values were lower than the device was capable of measuring as described in the manufacturer's manual. Therefore, we could not detect even the directional changes in rSO₂. His rSO₂ remained unmeasurable until 3 days after the operation with alert mental status and lowered bilirubin level. One study revealed that changes in serum bilirubin concentration do not influence the rSO₂ values during LT [10]. It seems likely that tissue pigmentation deposits may not disappear immediately in some patients [6]. Bilirubin can competitively absorb near infrared light and therefore play a role as confounder for rSO₂ measuring. Bilirubin itself cannot affect either cerebral blood flow or cerebral oxygen uptake [6,9]. Hemoglobin levels were maintained above 8 g/dl, with MAP above 70 mmHg. Clinical causes other than an underestimation of rSO₂ related to high bilirubinemia are hard to imagine.

The relationship between high serum bilirubin and falsely lower rSO₂ has been reported. However, a case in which rSO₂ was below the lower limit throughout LT and was maintained even after bilirubin diminished seem to be rare.

The limitation of this case report is that we did not use other methods for estimation of CBF such as transcranial Doppler sonography. We took it for granted the low rSO₂ was an artifact because the patient was alert. If we had used the transcranial Doppler, we could have definitively ruled out the possibility of cerebral hypoperfusion. Moreover, it is unclear how long it might take to normalize the rSO₂ after bilirubin decreased or what level of bilirubin is adequate for reliable rSO₂ in icterus patients. There is a need for further research.

In conclusion, severe hyperbilirubinemia may make it impossible to estimate cerebral oxygenation using NIRS devices and furthermore, this limitation would persist even after the bilirubin decreased. Careful attention should be paid to the interpretation of NIRS values in patients with severe hyperbilirubinemia during LT.
