Demonstration of Estrogen Receptor by Immunohistochemical Staining in Paraffin Sections of Breast Carcinoma

Woo-Ick Yang*, In Joon Choi*, Hyun-Ok Kim[1] and Kyong-Sik Lee[2]

Paraffin embedded sections of 64 breast carcinomas were stained immunohistochemically using a commercially available monoclonal antibody to estrogen receptor. To improve the sensitivity of the staining, the authors used a Pronase® enzyme pretreatment, biotinylated antibody to rat IgG as secondary antibody, streptavidin-alkaline phosphatase as tertiary reagent and fast red as chromogen. When compared to the results of estrogen receptor enzyme immunoassay, this method yielded an 85.9% concordance rate, 86.2% specificity and 85.7% sensitivity. When compared to estrogen receptor immunocytochemistry(ER-ICA) in frozen section and considering the inherent advantages of immunohistochemical staining over biochemical assay, the major advantages of this method are good morphology, suitability for retrospective study and reduced cost of staining due to dilution of expensive primary antibody. Thus, this method offers an alternative to ER assay using fresh tissue and should provide additional valuable information about estrogen receptor.

Key Words : Estrogen receptor, immunohistochemical staining, paraffin sections, breast carcinoma

The prognosis of breast cancer influenced by a variety of clinical and pathologic factors. Among these, the axillary lymph node status and the tumor size have been found to be the best prognostic indicators (Fisher *et al.* 1984). A recent important development in the evaluation and management of breast cancer is the realization that the presence of estrogen receptor(ER) correlates with the response to hormone therapy and prognosis(Jensen *et al.* 1971; Rubens and Hayward 1980; Knight *et al.* 1983; Lippmann and Allegra 1980; Osborne *et al.* 1980; Fisher *et al.* 1983; Howat *et al.* 1985). Although the significance of ER analysis in the treatment of breast cancer remains somewhat problematic, there is general agreement that receptor-rich tumors are more likely respond to endocrine therapy(Jensen *et al.* 1976; DeSombre and Jensen 1980; Jensen 1981; Jensen *et al.* 1982; Howat *et al.* 1985). The ER can be measured in vitro by various techniques such as sucrose density gradient(Jensen *et al.* 1971), dextran-coated charcoal assay(Korenman and Dukes 1970), gel electrophoresis(Wagner and Jungblut 1976) and gel filtration assay(Godefroi and Brooks 1973). The development of highly specific monoclonal antibodies to ER protein by Greene *et al.* (1980) has permitted the development of ER-radioimmunoassay(ER-RIA), ER-enzyme immunoassay(ER-EIA) and ER-immunocytochemistry(ER-ICA), based on direct antigen recognition(Greene and Jensen 1982; king *et al.* 1985). Several reports indicate that the results of these methods bear a semiquantitative relationship to those of biochemical assay(King *et al.* 1985; Goussard *et al.* 1986; Remmele *et al.* 1986; Thorpe 1987; Van Netten *et al.* 1987). Although ER-ICA using frozen sections showed encouraging and reproducible results, the use of frozen sections has several disadvantages, such as suboptimal histology, the need for fresh tissue and the lack of suitability for retrospective studies. So attempts have been made to develop a reli-

able ER-ICA technique which can be performed on formalin-fixed and paraffin-embedded tissue sections with encouraging results(Andersen *et al.* 1986; Shintaku and Said 1987; Cheng *et al.* 1988).

In this study we performed ER-ICA on paraffin-embedded tissue sections of breast cancer using commercially available kits. We compared the results with those of ER-EIA to determine the value of ER-ICA in paraffin-embedded tissue sections.

MATERIALS AND METHODS

Materials

The materials for this study came from 64 cases of breast carcinoma examined in the Department of Pathology of Severance Hospital from July 1988 to January 1990, for which ER analysis had been performed by ER-EIA. The histologic types of breast carcinoma included 59 cases of infiltrating ductal carcinoma-not otherwise specified, 2 cases of infiltrating lobular carcinoma, 2 cases of mucinous carcinoma and a case of medullary carcinoma. The ages of the patients ranged from 27 to 74 years (mean, 48.3 years). The patients were all women.

METHODS

ER-ICA of paraffin sections

Routine formalin-fixed and paraffin-embedded tissue blocks were cut at four microns, mounted on glass slides without tissue adhesives and dried in an oven at 60°C overnight. Slides were then deparaffinized for 15 minutes in xylene, hydrated through graded alcohols for 5 minutes and rinsed in 0.05M TRIS buffer (pH 7.5 at 25°C). Sections were then treated with 0.03 gm/ml of Pronase® enzyme (protease, Streptomyces griseus 50,000 units, CALBIOCHEM Corporation) in TRIS buffer for 10 minutes at 37°C. After TRIS buffer wash for 10 minutes, sections were incubated overnight at room temperature with primary antibody (ER-ICA Monoclonal, Abbott Laboratories) at 1 : 10 dilution. Slides were rinsed with TRIS buffer for 10 minutes,

and biotinylated antibody to rat immunoglobin G (VECTOR Laboratories) was added for 30 minutes followed by TRIS buffer washing for 10 minutes. Streptavidin-alkaline phosphatase (BioGenex Laboratories) was added for 30 minutes. After final wash, sections were then incubated in chromogen substrate solution (Fast red, BioGenex Laboratories) for 15 minutes. Sections were then washed in water, lightly counterstained with Mayer's hematoxylin and coverslipped with glycerin-jelly. A negative control was run during each procedure on some of the paraffin sections with the negative control antibody (normal rat serum) supplied in the Abbott Kit. Sections of stomach carcinoma were also stained as negative controls. After interpreting the results of staining by this method, we attempted several other methods using different combinations of reagents. The methods tried were as follows(Table 1).

ER-EIA

Fresh samples of breast tumor were sent to the department of clinical pathology at the time of surgery for estrogen receptor analysis using the ER-EIA monoclonal kit(Abbott Laboratories). Values of less than 20 femtomoles/mg cytosol protein were considered to be negative, while values of more than 20 femtomoles/mg cytosol protein were interpreted as positive.

Evaluation of ER-ICA

The results of staining were interpreted without knowing the results of ER-EIA. Stains were rated on the basis of visually estimated proportions of positive tumor cells as "+++" when more than two-thirds of tumor cell nuclei showed positive staining; "++" when approximately one-third to two-thirds of tumor cell nuclei showed positive staining; "+" when less than one-third of tumor cell nuclei were positive; and "0" when there was no tumor nucleus staining. For statistical analysis of the results, we regarded the results of staining as "positive" if any portion of the tumor cell nuclei showed positive staining. The staining intensity of tumor cell was interpreted as "++" when the tumor cell showed predominantly intense, opaque, red staining of nuclei and "+" when the tumor cell showed predominantly speckled red staining of the nuclei.

RESULTS

ER-ICA in paraffin section

The results of ER-ICA using paraffin-embedded sections are shown in Table 2. The quality of immunostaining was good, and it was easy to interpret the results of staining because of a clean background and good contrast of fast red dye even in tumors with weak staining. The positive reaction was confined to the nuclei of breast cancer cells (Fig. 1) and normal ductal epithelial cells (Fig. 2). No specific cytoplasmic staining reaction was observed and no nuclear staining occurred in negative controls. Heterogeneity of the staining reaction was conspicuous, and the percentage of positively stained neoplastic cells ranged from 0 to 100 percent. Among the 34 cases with positive ER-ICA staining, 3 cases showed "+" positivity, 7 cases showed "++" positivity and 24 cases showed "+++" positivity. The distribution of positive nuclei varied considerably even within the same section, and there was a tendency toward focal clustering of positive tumor cells. Positive tumor cells also showed considerable heterogeneity in the intensity of the reaction, and there was a tendency for tumors with high percentage of positive tumor cells to show intense staining of the nuclei. Non-neoplastic ductal epithelial cells also occasionally showed nuclear staining in both ER-positive and ER-negative tumors, and their staining intensity and the number of positive cells varied from case to case. Thirty-one of the 59 cases of infiltrating ductal carcinoma-NOS showed a positive reaction, both cases of mucinous carcinoma showed diffuse positive staining(Fig. 3), one of two cases of infiltrating lobular carcinoma showed positive staining and one case of medullary carcinoma showed a negative reaction. It was, however, difficult to correlate positivity with histologic type due to the small numbers of types other than infiltrating ductal carcinoma-NOS.

Using other combinations of reagents, pretreament enzyme and incubation time of primary antibody, we could not obtain results as satisfactory as with the original method.

Comparison of ER-ICA of paraffin sections with ER-EIA

The results of ER-ICA using paraffin sections were compared with content of ER measured by ER-EIA. As shown in Table 3., 30 of the 35 tumors with ER content greater than 20 fmol/mg cytosol protein displayed positive ER-ICA. Of the 29 tumor samples negative for ER(below 20 fmol/mg cytosol protein) by ER-EIA, 25 showed no immunoreactivity. Thus the results of ER-ICA agreed with those of ER-EIA in 85.9%, and the specificity and sensitivity using the results of ER-EIA as "true" values were 86.2% and

MEDU: Medullary carcinoma, IDC: Infiltrating ductal carcinoma-not otherwise specified,
MUCI: Mucinous carcinoma, ILC: Infiltrating lobular carcinoma

85.7% respectively. Five cases showed false negative results(ER-EIA positive, ER-ICA negative), and the values of ER-EIA were 22.5, 31.03, 38.90, 153.20 and 625.00 fmol/mg cytoplasmic protein. In one case with this false negative result(ER-EIA; 625.00 fmol/mg cytoplasmic protein), ER-ICA revealed intense positive nuclear staining of adjacent normal ductal epithelium while the nuclei of the tumor cells were totally negative(Fig. 4). On the other hand, four cases with negative ER-EIA(3.25, 6.80, 7.51 and 14.00 fmol/cytoplasmic protein) showed a positive ER-ICA.

The quantitative relationship between the semiquantitative values of ER-ICA(0, +, ++, +++) and the values abtained by ER-EIA is shown in Fig. 5. Statistical analysis using simple linear regression analysis showed the semiquantitative results of ER-ICA and the values of ER-EIA to be correlated(r: 0.35 $p < 0.001$).

DISCUSSION

The use of monoclonal antibody against estrogen receptor protein has permitted direct measurement of the amount of estrogen receptor protein by immunologic assay such as enzyme immunoassay and radioimmunoassay(Green *et al.* 1980; Jensen *et al.* 1982; Greene and Jensen 1982). Because these methods, like the previously used biochemical methods, require fresh tissue homogenates, they provide little information about the heterogeneity of ER distribution in tumor tissue. Also the bothersome and time-consuming procedures hinder wide clinical applications. The development of ER-ICA using frozen tissue sections makes it possible to correlate the histopathologic characteristics of a tumor with its ER status, even with very small amounts of tissue (King *et al.* 1985). Several studies with ER-ICA report that the results of immunostaining are significantly correlated with the concentrations of ER as measured by biochemical assay, so ER measurement by ER-ICA appears to be useful in predicting the response to hormonal therapy(King *et al.* 1985; McClleland *et al.* 1986; Pertschuk *et al.* 1985). Because this method works on fresh frozen tissue, it has suboptimal morphologic features and it is impossible to perform a retrospective study. Recent developments in the field of immunohistochemistry have led to technical modifications with increased sensitivity. Among these, the avidin-biotin methods are popular because of their increased sensitivity and versatility(Hsu *et al.* 1981). Due to the markedly increased sensitivity of these immunostaining methods, several antigens previously detected only in freash tissue can be demonstrated in routinely fixed and paraffin-embedded tissue, and several

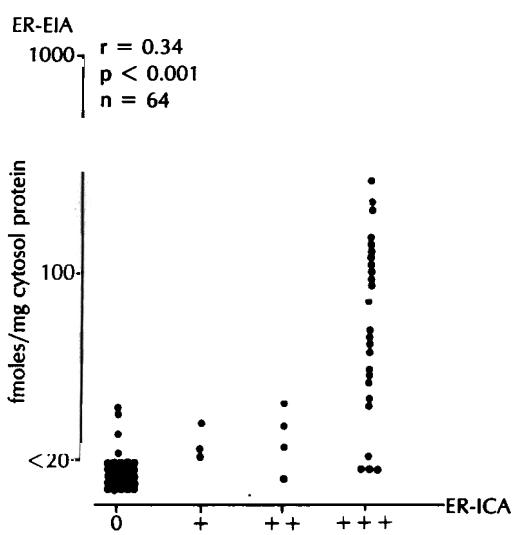

Fig. 5. Relationship between semiquantitative ER-ICA values and ER-EIA.

techniques were reported recently for the detection of estrogen receptor in paraffin sections using different combinations of reagents(Andersen *et al.* 1986; Shintaku and Said 1987; Cheng *et al.* 1988). In this study we used the enzyme-labelled avidin method, the most sensitive method yet known (Giorno 1984), and Pronase® enzyme pretreatment to demonstrate estrogen receptor in formalin-fixed tissue using monoclonal antibody directed against estrogen receptor.

The results of this study indicate that ER-ICA using paraffin embedded sections is a reliable method having many advantages over other ER assay methods. The concordance rate, specificity and sensitivity of this method using the results of ER-EIA as "true" values were 85.9%, 86.2% and 85.7% respectively. Four cases with ER-EIA values below 20 fmol./mg cytosol protein showed positive nuclear staining using our method. These false positive cases demonstrated nuclear staining over at least 60 % of tumor cells, however, we believe that this may be an indication of the limitaions of ER-EIA rather than actual false positivity. Five cases with

ER-EIA values over 20 fmol/mg cytosol protein showed no nuclear staining of tumor cells. The ER-EIA values of these false negative cases ranged from 22.5 to 625.00 fmol/mg cytosol protein. The false negativity associated with low ER-EIA values may be due to loss of immunoreactivity resulting from fixation and paraffin-embedding procedures. But in view of the ER-ICA positivity in four cases with ER-EIA values below 20 fmol/mg cytosol protein, we believe other factors may be a cause of this discrepancy. In one case (ER-EIA value 625.00 fmol/mg cytosol protein), the ER-ICA showed intense positivity within the adjacent normal ductal epithelium without positive staining of tumor cells, indicating a high ER-EIA value due to the high ER content of normal epithelial cells. The sensitivity and specificity of ER-ICA using paraffin sections may therefore be higher than that indicated by the results of this study.

Other methods using different combinations of commercially available reagents did not show results as reliable and reproducible as that of the original one. Although antibody to mouse immunoglobulin is reported to cross-react to antibody to rat immunoglobulin, and some reported good results with anti-mouse immunoglobulin instead of anti-rat immunoglobulin (Wang *et al.* 1988), we could not obtain results as satisfactory as the original one. With short incubation times(1 hour), we could not obtain satisfactory results using a combination of reagents. Thus in view of the high cost of primary antibody, it is preferable to perform overnight incubations with 1:10 dilution of primary antibody. Pronase® enzyme pretreatment allows exposure of double-stranded DNA and increases the sensitivity of immunostaining with paraffin-embedded tissue. We tried trypsin enzyme pretreatment instead of Pronase®, but we failed to obtain satisfactory results. Other combinations of secondary and tertiary reagents, such as the ABC and PAP methods, did not show reliable results due to the inherent sensitivity of the methods.

We conclude that the application of Pronase® enzyme pretreatment and the alkaline-phosphatase labelled avidin biotin method to ER-ICA in paraffin-embedded sections offers an alternative to ER-ICA using frozen section, ER-EIA, ER-RIA and other biochemical assays. We feel that its major advantages, such as reduced cost of staining due to dilution of expensive primary antibody, good morphologic detail; suitability for retrospective study, technical simplicity, and abilty to correlate histologic characteristics of a tumor and status of ER even with a very small amounts of specimen will provide valuable additional information about estrogen receptors.
